Paleoageography and Climatic Change recorded on Viviparidae Carbon and Oxygen Isotope in Mae Moh Coal Mine, Northern Thailand

Benjavun Ratanasthien, Isao Takashima and Osamu Matsubaya

Abstract: Viviparidae fossil collected from the R-, Q-, and K-coal zones of the Mae Moh coal mine, northern Thailand were analyzed for $^{13}$Carbon and $^{18}$Oxygen isotopes at Akita University, Japan. The result reveals that Viviparidae of the lower part of the coal mine contribute much heavier carbon isotopes than the upper part. The results revealed that Viviparidae shell $^{13}$C values are between 3.52 to 6.92 ‰ PDB in the R-coal zone, between 4.17 to 5.77 ‰ PDB in the Q-coal zone and between 1.41 to 1.34 ‰ PDB in the K-coal zone. For oxygen isotopes the lower part of the basin showed heavier isotopes than the upper part, where the $^{18}$O values are between -3.15 to -5.10 ‰ PDB in the R-coal zone, between -4.19 to -6.04 ‰ PDB in the Q-coal zone, and between -7.05 to -8.04 ‰ PDB in the K-coal zone. The isotope valued of Viviparidae shells collected in the Kew Lom reservoir in the Lampang area yielded $^{13}$C values between -11.01 to -12.19 ‰ PDB and the $^{18}$O ‰ value between -6.64 to -7.04 ‰ PDB. The isotopic results of Viviparidae fossil shells from the Mae Moh basin show the gradually change from the R-coal zone to the Q-, and the K-coal zone and significantly different from the Recent Viviparidae in the area. The heavy carbon isotopes in the R-coal zone could imply a much cooler climate than during the Q- and K-coal zone depositing period and the area were more close to the sea. The climatic condition during the Q- and K-coal zone depositing period was warmer and at a geographically higher elevation or latitude than during depositing the R-coal zone. The changing records in Mae Moh coal field are confirmed by temperate fossils in the other Oligocene to Lower Miocene basins in Northern Thailand. The change to a more tropical climate could have occurred during the Middle Miocene period, as indicated by paleomagnetic age dating in the K- and Q-coal zone. The northward movement of the Australian-Indian plate and collision with the Eurasian plate are suspected to be the main cause of the change.

Keywords: carbon isotope, oxygen isotope, Viviparidae, climatic change, paleoageography, Mae Moh coal mine, Miocene, Australian-Indian plate, Eurasian plate, Thailand

1. Introduction

The Mae Moh coal mine is operated in the largest coal deposit in Thailand. It is situated in Mae Moh basin, Lampang province, northern Thailand. Each day, and approximately 40,000 tons of coal of lignite to sub-bituminous C in rank (ASTM, 1988) are mined for 10 units coal-fired power plants (total of 2400 MW) in the mining area. The mine pit covers an area of 4 x 8 km$^2$ at depths varied up to 200 meters. During the exploration drilling and excavation, there were many shell beds, mainly gastropods, which have been found associated with the coal beds, and some of these are used as key beds. The important shell beds used as keys beds are those below the R-coal zone, below the Q-coal zone, and the most important bed, due to the great thickness of Viviparidae shell (maximum 12 meters), lying between the K3- and K4-coal zone. During the mining history, this shell bed has shown to be only 4 meters thick in the northeastern pit. Later, when the southwest pit was opened, the largest part of the shell bed in terms of thickness and width, consists of nearly 100 percent pure Bellemya sp. without clays intercalation are shown (Plate 1). The environment of depositions of these shell beds become interested and required investigation. Isotopic analysis is one of the tools in this investigation. The important of this method is the possibility to interpret the role of changing depositional environment.

2. Geology of the Mae Moh Basin

Mae Moh coalfield is the largest Tertiary coal deposit

$^1$Department of Geological Sciences, Faculty of Science, Chiang Mai University, Chiang Mai, 50200, Thailand: E-mail: benjavunr@hotmail.com

$^2$Center for Geo-Environmental Science, Faculty of Engineering and Resource Science, Akita University, 1-1 Tegataagaken, Akita 010-8502 Japan
in Southeast Asia. It is located at latitude 18°18'21"N, longitude 99°44'02"E, in Mae Moh District, Lampang Province, approximately 631 kilometers north of Bangkok and 26 kilometers east of Lampang township. The basin is bounded mostly by marine Triassic rocks of Lampang Group (Fig. 1), which are composed of limestone, shale, and sandstone. Exceptionally, in the southern part of the basin, the Tertiary sequence is overlain by the Quaternary basalt (Sasada et al., 1987; Charoenprawat et al., 1995; Chaodamrong and Burrett, 1997). Unconsolidated sediment of fluviatile deposits form a thin veneer throughout the basin. It consists of superficial gravel deposits in the lower part, lacustrine to fluviolacustrine in the middle part and alluvium deposits in the upper part (Chaodamrong, 1985; Jitapankul et al., 1985; Uttamo et al., 2003).

The Tertiary sequences of Mae Moh basin (Mae Moh Group) have been divided into three formations (Fig. 2). Each formation consists of sediments that strongly differ in lithology, sedimentary structures, degree of con-

Fig. 1 Geologic map of Mae Moh basin (modified from Charoenprawat et al., 1995).
solidation, and fossils, as described below from the lower to upper parts (Chaodumrong, 1985; Jitapankul et al., 1985; Songtham et al., 2005a and b; Silaratana et al., 2004, 2004), as shown in Figs. 1, 2 and in the following descriptions:

### 2.1 Huai King Formation

It is the lowermost formation of the Tertiary succession that unconformably overlies the basement rock, the Lampang Group. The typical character is a fining upward sequence grading from conglomerate to mudstone or claystone on top. It is variegated in color, red, gray, green, yellow, blue and purple, common calcicrete

</table>
in part, slightly calcareous cement, no macrofossils (except on the southern part found abundant \textit{Viviparus} sp. in the lower portion of this formation). The thickness is varied from less than 15 meters on the border to 150 meters on the central part of the basin (Jitapankul et al., 1985). The uppermost part of the formation is marked by a thin layer of coal named the O-Zone which occurs locally.

\textbf{2.2 Na Khaem Formation}

This Formation is the major coal deposit of the Mae Moh basin, and consists of semi-consolidated mudrock and five coal zones with varying thickness of 250 to 400 meters. Two of these coal zones are the major production of this mine. Jitapankul et al. (1985), Chaodamrong (1985), and Evans and Jitapankul (1990) divided this formation into three members as describe from lower part to the upper part:

\end{table}

Fig. 2 Stratigraphic succession of Mae Moh coal mine (modified from Jitapankul, et al., 1985).
Member III (Underburden) is a sequence of gray to greenish gray claystone and mudstone with a thin layer of coal of sub-bituminous rank, named the R-Zone. These beds are laminated to thick bed, planar type, highly calcareous, in the upper part with abundant gastropod beds, fish remains, ostracod, plant roots, intraformational conglomeratic texture and intermixed color texture near a coal seam or lignitic layer, burrow and boring, and load cast. At the Underburden / Q-Zone boundary downward is the ? Paludina Molluscan Zone of Songtham et al. (2005b). They suggested that the Mae Moh basin was a lake along a shallow shore in quiet conditions without any vegetation growing nearby. The thickness varies from 150 to 230 meters.

Member II is the most economically attractive coal sequence and is separated into three portions: Q-Zone, Interburden, and K-Zone.

The Q-Zone is a lower portion of coal that is black to brownish black and brittle, with abundant siliceous calcareous diatoms, the pyritized gastropod Viviparusspp., and Planorbiidae and plant remains. It is interbedded with coal of sub-bituminous rank, with partings (about 30%) of light brown claystone/silty claystone. Technically the seams are divided into Q-1 to Q-4 with total thickness that vary from 25 to 30 meters. However, it separates to the north and south with thicker silty mudstone and changes laterally from coal layers to carbonaceous claystone and clay. The Planorbiidae Molluscan Zone is located at the Underburden / Q coal boundary and the K-4 / K-3 boundary. Planorbiidae are common in places, especially under the Q coal bed. This implies a swampy environment containing sparse to densely distributed vegetation (Songtham et al., 2005a, b). A proboscidean fossil was discovered in the Q-2 Subzone (Permsook, 2007 personal communication).

The interburden is a sequence (10 to 30 meters thick) of brown, brownish gray, gray, green and greenish gray claystone that lies between the two major coal seams. These beds are laminated to thick-bedded, planar type, with common lignite flakes, fish remains, plant roots, rare ostracod, common intraformational conglomeratic texture on the lower part, common gastropods (Viviparus sp.), load cast, and abundant micro slip planes. This sequence is thicker in the east flank but thinner in the west flank of the main basin. The K-Zone is a sequence of black to brownish black, brittle, high calcareous coal in the upper part. Diatomite flourishes in the eastern part and can be used to separate the K-Zone into four layers, and there are common gastropods (Planorbis sp., Mellanooides sp., and Viviparus sp.) and rare fish remains and plant remains. This zone is interbedded with some coal of sub-bituminous rank with partings of light yellowish gray to gray silty claystone. The thickness varies from 10 to 30 meters. However, it is split in the north and south with thicker silty claystone partings and a lateral change to carbonaceous claystone and clay. The coal series are named K-1 to K-4. The K-4 Subzone of thin coal layer is the end of the Planorbiidae Molluscan Zone. It was interpreted as a swamp deposit (Songtham et al., 2005a, b). Between the K-3 and K-4 Subzones, the thick Viciparidae beds of Bellamyawere were deposited. The thickest layer is about 12 meters, deposited in the southwest margin of the coal pit. In K-3 and K-2 were found Planorbis sp. In K-2, Planorbiidae occurred widely associated with Paludina in carbonaceous claystone. All taxa are missing from the carbonaceous claystone K-1 where mastodont remains, the skeletons of mastodons with tusks and molars were discovered in this K-Zone (Songtham et al., 2005a, b). At the boundary of the K-1 Subzone and the overburden claystone indicated is Melanosidessp., cf. M. tuberculata Molluscan Zone. This zone is covered by the overburden claystone and J-Zone. The sulfur isotope of pyrite from the Q-zone, K-zone, and the lower part of J-zone indicate the source of sulfur was from organic sulfur inferring in the freshwater environment (Silaratana et al., 2004).

Member I is the uppermost of Na Khaem Formation. The coal beds of J-Zone are thin and not much economic. J-Zone consists of six sequences of gray and greenish gray claystone, mudstone, and occasional siltstone and coal (J-1 to J-6). These beds are laminated to massive, planar type, highly calcareous, with fine grain pyrite spots common in some part, and with abundant gastropods (Mellanooides sp., Physa sp., Viviparus sp.), fish remains, ostracod, plant remains, reptile skeletal elements, load structures, intraformational conglomeratic texture of pumice and volcanic debris, and intermixed color texture near coal seams or coal layers, burrows and borings. The thickness is about 100 to 150 meters. The upper part of this zone consists of two thin argillaceous layers (thickness less than 2 meters) and 13 thin seams of coal within J-1 to J-6. The sulfur isotope from the middle part of the J-zone indicate a volcanic source, and then in the upper part the sulfur isotope may indicate a marine incursion or opening of the basin during coal deposition (Tankaya, 2001, Silaratana et al., 2003; 2004).

2.3 Huai Luang Formation

This formation was call the “red bed” by Longworth-CMPS Engineers (1981), It is the uppermost formation which consists of red to brownish red, semi-consolidated and unconsolidated claystone, siltstone, and mudstone with some lenses of sandstone and conglomerate, with some gray layer interbeds in some parts. No macrofossils were found but abundant gypsum and pyrite, rare roots and flame structures exist. The thickness of this unit varies from less than 5 to 350 meters. It is thickest in the central part of the main and western sub-basin, thinning rapidly towards the eastern and western margins, where it is entirely absent from the stratigraphic sequence or only a few meters thick. The
upper part of the “red bed” is the coal I-Zone with an abundance of Margarya mollusks, partly pyrititized (Songatham et al., 2005b), about 50-150 cm thick and found especially where the sequences are completely present. Longworth-CMPS Engineers (1981) concluded that their red/brown colors are likely to be due to the oxidation of fine-grained pyrite and hematite disseminated throughout certain layers within the formation. However, the results of sulfur isotope deduce from the red bed zone indicated a sulfur source from marine vaporized sulfate, but from pyrite in gastropod from the I-zone coal indicated a sulfur source from bacterial reduction of sulfate to sulfur (Silaratana et al., 2003, 2004).

2.4 Coal Quality

The coal quality at Mae Moh is classified as low coal, not only low rank but also low quality, suitable only for feeding coal-fired power plants, due to a high ash and sulphur content. The proximate analysis of Mae Moh coal varies: moisture 15-33%, ash 11-34%, volatile matter 18-40%, and fixed carbon 6-36%. The sulphur content varies from 1-5% and calorific values between 1,750-4,250 cal/gm. Vitrinite reflectance is between 0.34-0.40 %Ro. Coal petrography indicates that a majority of macerals are densinite and gelinite with an abundance of alginite, sporinite, liptodetrinite, but rare inertinite. The mineral matter shows an abundance of frambooidal pyrite, especially in J coal zone.

2.5 Age of Mae Moh Basin

The age of the Mae Moh coal has been given by Ginsburg et al. (1983) to be Middle Miocene, deduced from its association with Stegolophodon sp. Later, paleomagnetic investigations of the Mae Moh basin (Benammi et al., 2002), in the lower third of the Na Khaem Formation, and continuing into the Huai Luang Formation showed that this sequence correlates on the geomagnetic polarity time scale from the C5Acn chron to C5An.2n chron, (Fig. 3), between 13.5 and 12.1 million years ago. The average sedimentation accumulation rate is about 17.5 cm/ka, and ages of 12.5 and 12.8 million years ago can be extrapolated to the fossiliferous levels (J-5 and K-1, K-2 coal).

3. Methodology

Viviparidae shells from Mae Moh Mine are selected from stratigraphic sequences in the open pit. The collected samples were from the under R-zone, Under Q-Zone and the thick Bellemuya bed in the K-zone. The samples of living fresh water mollusks were collected from the Kew Lom Reservoir, about 40 km. north of Mae Moh. Shell samples were crushed into powder to determine the mineral contents in the shells using x-ray diffractometry. The isotopes $^{13}C/^{12}C$ and $^{18}O/^{16}O$ were analyzed from dissolved, crushed shells by mass spectroscopy at the Center for Geo-Environmental Science, Faculty of Engineering and Resource Science, Akita University, 1-1 Tegatagakuen, Akita 010-8502 Japan.

3.1 Mineral determination

The samples were crushed and underwent $d$-spacing determination using a Rigogu x-ray diffractometer. The conditions used Cu K $\alpha$ radiation with voltage of 40 kv and 20 mA., slit width DS 1 RS 0.3 S.S 1, scan speed 2 degree/min and step/sample 0.2 degree. The samples were scanned from 2 degree 2 to 60 degree 2. The diffraction peaks were converted to $d$-spacing and the mineral contents were identified by comparing the set of $d$-spacing with the ASTM XRD Powder Data File.

3.2 Isotopic analysis

Approximately 25 milligram of samples were weighed and placed at the bottom part of the two arms of the reactor tube. Two milliliters of phosphoric acid were placed in the side arms. The reactor tubes were vacuumed until no gas or vapor were left in the reactor before placing them to reach equilibrium at 25 °C water bath. The reactor tubes were tilted, allowing the acid to react with the samples and were left in the water bath for complete reaction. The carbon dioxide gas from the reaction was purified using the cryogenic process with the aid of liquid nitrogen (temperature -190 °C), a mixture of dry ice and acetone (temperature -88 °C), and a vacuum pump. The volume of gas obtained from the reaction of each sample was measured for its percentage yield. The purified carbon dioxide was kept in an air-tight glass tube waiting for analyze by mass spectrometer for carbon and oxygen isotopes. The 12 Asc-2 L. No. 3 Carbon -oxygen isotopic standard was used to convert the isotopic ratio to PDB.

4. Results and Discussion

4.1 Mineral identification

The results of x-ray diffraction reveal the shells of Viviparidae in Mae Moh area, both fossils and Recent, are composed of only the single mineral aragonite.

4.2 Isotopic analysis

The isotopic results are shown in Table 1. The results reveal the Viviparidae shell $^{13}C$ values in Mae Moh Mine are between 3.52 - 6.92 ‰ PDB with the average of 5.52 ‰ PDB in the R-coal zone. In the Q-coal the $^{13}C$ value are between 4.17 - 5.77 ‰ PDB with the average of 5.12 ‰ PDB, which indicates a heavy isotope. In the K-coal zone the $^{13}C$ values are between 1.41 - 3.34 ‰ PDB with an average of 2.38 ‰ PDB. For oxygen isotopes the lower part of the basin showed the heavier isotope than the upper part, where the of $^{18}O$ values are between -3.15 and -5.10 ‰ PDB with an average of -
3.74 ‰ PDB in the R-coal zone, between -4.19 and -6.04 ‰ PDB with an average of -5.41 ‰ PDB in the Q-coal zone, and between -7.05 and -8.04 ‰ PDB with an average of -7.91 ‰ PDB in the K-coal zone. The isotope value of a Viviparidae shell collected from the Kew Lom reservoir in the Lampang area yielded $^{13}$C values between -11.01 and -12.19 ‰ PDB with an average of -11.65 ‰ PDB and $^{18}$O ‰ values between -6.64 and -7.04 ‰ PDB with an average of -6.76 ‰ PDB.

The isotopic results of Viviparidae fossil shells from the Mae Moh basin show a gradually change from the R-coal zone to the Q-, and the K-coal zone and significantly differ from Recent Viviparidae in the area. The heavy carbon isotope in the R-coal zone may imply a much cooler climate than during the Q- and K-coal zone deposition period when the area was much closer to the sea, especially when compared to the $^{13}$C in the foraminifera (Srinivasan and Chaturvedi, 1990). Climatic conditions during Q- and K-coal zone deposition period were warmer and at a higher elevation or latitude than during deposition of the R-coal zone, as seen by the depletion of oxygen isotopes and enrichment of carbon isotopes (Andrusevich et al., 2000). The changing records in the Mae Moh coal field are confirmed by temperate plant

Table 1 Result of carbon and oxygen isotopic analysis of Viviparidae from Mae Moh area.
The age of the floras is Late Oligocene to Early Miocene. The change to a more tropical climate observed in Mae Moh stratigraphy, as recorded by the palynological assemblage (Meesuk, 1986; Watanasak, 1988; Songtham et al., 2005a, b) may have occurred during the Middle Miocene, as indicated by paleomagnetic age dating in the K- and Q-coal zone (Benammi et al., 2002, 2003; Fig. 3).

The beginning of northern Thailand segment movement from the warm temperate area is not clearly understood. However, the age dating of the Mae Ping Fault zone at 29-31 Ma (Lacassin et al., 1997; Ahrendt et al. 1993, 1994, 1997) may be the closest related events. The northward movement of the Australian-Indian plate and collision with the Eurasian plate, and the westward subduction of the Pacific plate, are suspected to be two major causes of the splitting and pushing of the northern Thailand segment southwestward along the Sakiang, Mae Ping and Red River Fault zones.

Acknowledgements: The authors would like to thank the Faculty of Engineering and Resource Science, Akita University, Japan, for a visiting professorship for Benjavun Ratanasthien, to the Mae Moh Mine Authority, Department of Mineral Resources, Thailand, for allowing the working group to collected fossil shell samples in the mining pits, and to the Department of Geological Sciences, Chiang Mai University, for allowing the group to present this paper at Tsukuba on 1-3 October, 2007.

タイ北部マエモー炭鉱産タニシ類化石の炭素・酸素同位体
に記録された古生物地理と古気候の変化

ベンジャヴァン ラタナシェーン・高嶋 助・松葉谷 治

要 旨

タイ北部のマエモー炭鉱の R、Q、K-石炭帯から産出したタニシ類化石の炭素 13・酸素 18 の同位体分析を秋田大学で
行った。その結果、下部層の方が重い炭素同位体比を示し、R-石炭帯の炭素同位体比は 3.52-6.92 % PDB で、Q-石炭帯
では 4.17-5.77 %、K-石炭帯では 1.41-1.34 % PDB 値を示した。酸素同位体比は下部層が上部層より重い値を示し、R 帯
で 3.15〜5.10 %、Q 帯で 4.19〜6.04 %、さらに K 帯では 7.05〜8.04 %の範囲を示した。

これらのランパン地域のケウム鉱床のタニシ類化石の同位体は炭素 δ 13C 値で-11.01〜-12.19 %、δ 18O 値で 6.64
〜7.04 %の範囲を示した。これらの結果、マエモー堆積盆地では、R 帯から Q 帯、そして K 帯へと徐々に同位体が変化
しており、さらに現在のタニシ類の同位体比とは明らかに異なる値である。この R 帯の重い炭素同位体比は、Q 帯や K
帯の堆積時より、より冷温であったことを示し、さらに当時の古地形は海に近い環境であったと考えられる。さらに Q
帯と K 帯の堆積時は、R 帯と比べて温暖化し、さらに地理的に高緯度化したか高度を増したことが考えられる。これら
のマエモー炭鉱での古気候変化は、タイ北部の他の更新新から下部中新統にかけての環境変化と同調的である。さらに、
より温暖な熱帯気候による気候変化は K 帯と Q 帯の古地磁気層序年代から指示される中期中新世に生じている。これらの古環
境変化的原因は、オーストラリアインドプレートの北上に伴うユーラシアプレートとの衝突によって生じたものである
と考えられる。
